EventReflex-DroneNav

Event-Based Perception and Spiking-Inspired Decision Making for Low-Power Autonomous UAVs

> Author: **Ayushman M.** (https://github.com/aymisxx)

> https://ayushmanmishr.wixsite.com/portfolio

---

1. Motivation

Autonomous aerial vehicles operating in real-world environments face strict constraints on:

- **perception latency**, where delayed sensory processing directly degrades control performance and safety,
- **onboard power consumption**, limiting mission duration and payload capacity,
- **robustness to lighting variation and motion**, including high dynamic range scenes, fast ego-motion, and motion blur,
- **deployable compute at the edge**, where size, weight, and power (SWaP) constraints prohibit large GPU-class processors.

Traditional perception pipelines based on frame-based RGB cameras and convolutional neural networks (CNNs) sample and process full images at fixed frame rates, regardless of scene dynamics. This design leads to several well-documented inefficiencies:

- **redundant computation**, as large portions of consecutive frames often remain unchanged,
- **increased perception-to-action latency**, due to frame acquisition, buffering, and batch processing,
- **high power consumption**, particularly for dense CNN inference on embedded platforms.

These limitations have motivated increasing interest in **neuromorphic vision and computing**, inspired by biological sensory systems, where perception is inherently asynchronous, sparse, and event-driven.

Event-Based Vision

Event-based cameras (also known as neuromorphic or silicon retina sensors) operate by asynchronously reporting changes in log-intensity at individual pixels rather than transmitting full image frames. Seminal work by Lichtsteiner et al. introduced the Dynamic Vision Sensor (DVS), demonstrating microsecond-level temporal resolution, high dynamic range, and sparse output characteristics. Subsequent surveys and experimental studies have shown that event cameras are particularly well-suited for high-speed robotics, agile flight, and resource-constrained platforms.

Event-based perception has been successfully applied to:

- visual odometry and SLAM (Gallego et al., IEEE TPAMI 2022),
- high-speed UAV navigation (Falanga et al., Science Robotics 2020),
- obstacle avoidance and optical flow under extreme lighting conditions.

These results consistently demonstrate **lower latency and improved robustness** compared to frame-based pipelines, especially in scenarios involving fast motion or challenging illumination.

Spiking Neural Networks and Neuromorphic Compute

Spiking Neural Networks (SNNs) represent information using discrete spike events and temporal dynamics rather than continuous activations. This paradigm aligns naturally with event-based sensing and enables:

- **sparse computation**, as neurons are active only when driven by meaningful input,
- **temporal processing**, capturing motion and dynamics without explicit frame differencing,
- **energy-efficient inference**, particularly when deployed on neuromorphic hardware.

Foundational work by Maass established the computational equivalence and temporal advantages of spiking neurons, while more recent studies have demonstrated competitive performance of SNNs on perception tasks when combined with event-based inputs (e.g., Rueckauer et al., Frontiers in Neuroscience 2017).

Neuromorphic processors such as Intel Loihi and BrainChip Akida have further shown that SNN-based inference can achieve **orders-of-magnitude reductions**

in power consumption compared to conventional accelerators for certain workloads, making them attractive for edge robotics and UAV applications.

Motivation for This Work

Despite significant advances, much of the existing neuromorphic robotics literature focuses either on:

- isolated perception modules, or
- hardware-specific demonstrations with limited system-level integration.

There remains a gap between **neuromorphic perception research** and **end-to-end autonomous decision-making pipelines**, particularly in a form that is:

- minimal,
- interpretable,
- and deployable.

This notebook addresses that gap by presenting a **minimal, simulation-based neuromorphic autonomy pipeline**, built using a custom lightweight navigation environment, to demonstrate:

> how event-based perception and spiking-inspired decision making can be integrated into a closed-loop autonomous drone navigation system.

The emphasis is deliberately placed on **conceptual correctness, architectural clarity, and system-level reasoning**, rather than hardware-specific optimization or benchmark performance. This design choice reflects real-world engineering workflows, where algorithmic validation and architectural feasibility precede hardware deployment.

---

2. Simulation Environment Overview

The environment used in this notebook models a simplified drone navigation task with the following properties:

- The drone is modeled as a **point agent** moving in a 2D plane at fixed altitude.
- The environment contains a **scalar field** representing spatially varying terrain utility (e.g., vegetation density, signal strength, or resource value).
- At each timestep, the agent observes a **local 128×128 spatial patch**

centered on its current position.
- The action space is **discrete**, consisting of four motion primitives:
    - up, right, down, left.
- The environment maintains a **visited mask** to track coverage.

Reward Structure

Reward is issued only on **first visit** to a location:

$$ r_t = \begin{cases} U(x_t, y_t), & \text{if the location has not been visited before} \\ 0, & \text{otherwise} \end{cases} $$

where $U(x,y) \in [0,1]$ is the underlying utility field.

This formulation encourages:

- exploration,
- spatial coverage,
- preference toward high-utility regions.

The environment is intentionally simple, serving as a controlled testbed for perception-to-action pipelines rather than a high-fidelity flight simulator.

---

3. Event-Based Vision: Conceptual Background

3.1 Event Cameras

Event cameras (neuromorphic vision sensors) operate fundamentally differently from conventional cameras.

Instead of capturing full image frames at fixed intervals, each pixel independently reports an **event** whenever the change in log-intensity exceeds a contrast threshold:

$$ \log I(x,y,t) - \log I(x,y,t_{\text{last}}) \ge C \quad \text{(ON event)} $$

$$ \log I(x,y,t) - \log I(x,y,t_{\text{last}}) \le -C \quad \text{(OFF event)} $$

Each event is represented as:

$$ e_i = (x_i, y_i, t_i, p_i) $$

where:

- (x_i, y_i) is the pixel location,
- t_i is the event timestamp,
- $p_i \in \{+1, -1\}$ denotes polarity.

Key properties of event cameras include:

- asynchronous output,
- microsecond-level timestamp resolution in hardware,
- very high dynamic range,
- sparse, low-power data generation.

3.2 Synthetic Event Generation in Simulation

Because this notebook operates entirely in simulation, event-based sensing is approximated using **temporal contrast** between consecutive observations.

Let:

- $I_t \in [0,1]^{128\times128}$ be the floating-point observation patch at time t,
- I_{t-1} be the observation from the previous timestep.

We compute the temporal difference:

$$ \Delta I_t = I_t - I_{t-1} $$

Synthetic events are generated via thresholding:

$$ E_t^{+}(x,y) = \mathbb{1}[\Delta I_t(x,y) > \delta] $$

$$ E_t^{-}(x,y) = \mathbb{1}[\Delta I_t(x,y) < -\delta] $$

This produces a **two-channel event representation**:

- positive events (increasing intensity),
- negative events (decreasing intensity).

Although simplified, this preserves the essential principle of event-based vision:

> information is encoded as *change over time*, not absolute state.

---

4. Neuromorphic Computation: Spiking-Inspired Models

4.1 Spiking Neural Networks (SNNs)

Spiking neural networks process information using discrete spikes instead of continuous activations.

A commonly used neuron model is the **Leaky Integrate-and-Fire (LIF)** neuron.

Continuous-time form:

$$ \tau_m \frac{dV(t)}{dt} = -V(t) + R I(t) $$

Discrete-time implementation (used in practice):

$$ V_{t+1} = \alpha V_t + (1 - \alpha) I_t, \quad \alpha = e^{-\Delta t / \tau_m} $$

Spike generation and reset:

$$ S_t = \mathbb{1}[V_t \ge V_{\text{th}}], \quad V_t \leftarrow V_t (1 - S_t) $$

Key advantages:

- sparse computation,
- inherent temporal dynamics,
- natural compatibility with event-driven inputs.

4.2 Role of SNNs in This Project

In this notebook, the spiking-inspired network is **not treated as a full flight controller**.

Instead, it functions as:

- a low-latency **perception-to-decision module**,
- mapping event representations to discrete navigation actions.

This reflects realistic autonomous system design:

- neuromorphic components handle perception and rapid decision making,

- classical control layers handle stabilization and actuation.

---

5. Control Architecture (System-Level View)

The overall autonomy loop implemented here is intentionally hybrid:

1. **Environment dynamics**
    - The drone moves within the 2D utility field.
2. **Event-based sensing**
    - Temporal contrast generates synthetic events.
3. **Spiking-inspired inference**
    - Events are encoded and processed by an SNN-like model.
4. **Action selection**
    - A discrete navigation action is chosen.
5. **Environment update**
    - Reward is computed and the state advances.

This separation ensures:

- interpretability,
- modularity,
- alignment with real-world hardware constraints.

---

6. Learning Strategy

To keep the implementation minimal and realistic, learning is staged:

Stage 1: Demonstration (This Notebook)

- Event generation from spatial observations.
- Spiking-inspired forward inference.
- Closed-loop rollouts in the environment.
- Visualization of:
    - event maps,
    - spike activity,
    - agent trajectories.

Stage 2: Distillation (Future Work)

- Train a conventional RL policy using frame-based observations.
- Collect state-action trajectories.
- Train the SNN to imitate the learned policy via behavior cloning.

This follows a common **train-large / deploy-efficient** paradigm.

---

7. Expected Outcomes

By the end of this notebook, we expect to demonstrate:

- A functioning **event-based perception pipeline**.
- A **spiking-inspired decision module** operating on event data.
- A complete **closed-loop autonomous navigation demo** in simulation.
- Clear separation between perception, decision making, and control.

Although minimalist, this establishes:

> conceptual validity, architectural clarity, and a direct path toward neuromorphic hardware deployment.

---

8. Limitations and Future Extensions

Limitations:

- Synthetic events approximate, but do not fully replicate, real event-camera behavior.
- No explicit power or latency benchmarking is performed.
- Hardware-specific constraints are not yet enforced.

Future extensions:

- real event-camera datasets,
- hardware-in-the-loop testing,
- multi-agent neuromorphic coordination,
- mapping to dedicated neuromorphic accelerators.

This notebook is intentionally minimal.

Its purpose is to demonstrate *understanding, feasibility, and system-level design*, not to maximize benchmark performance.

Satellite-Driven Navigation Environment

Why replace the random field?

A randomly generated utility field is sufficient for debugging, but it fails to capture the spatial structure, correlations, and gradients present in real environments.

Since the goal of this project is to demonstrate **event-based perception and neuromorphic decision-making**, it is essential that the underlying environment contains **real visual structure** that produces meaningful temporal contrast and events.

Therefore, in this combo we replace the synthetic field with a **utility map derived from real satellite imagery**.

Data Assumptions

- A single RGB satellite image is placed in:
  ```
  data/
  └── satellite.png
  ```
- The image represents land cover at a fixed resolution.
- Near-Infrared (NIR) is assumed unavailable.

Utility Field Construction (VARI)

We derive a vegetation-like utility field using the **Visible Atmospherically Resistant Index (VARI)**:

$$ \text{VARI} = \frac{G - R}{G + R - B + \varepsilon} $$

where $R, G, B \in [0,1]$ are the normalized color channels.

The resulting VARI map is:

- clipped to a valid range,
- normalized to $[0,1]$,
- treated as a **spatial utility field** $U(x,y)$.

This field represents regions of higher or lower desirability for exploration.

Environment Model

- The drone is modeled as a **point agent** in a 2D grid.
- At each timestep, it observes a **local spatial patch** of size $P \times P$.
- The action space consists of four discrete motions:
- up, right, down, left.
- The agent is constrained to remain within the image boundaries.

Reward Structure (First-Visit Utility)

Reward is granted only on first visit to a location:

$$ r_t = \begin{cases} U(x_t, y_t), & \text{if the cell has not been visited before} \\ 0, & \text{otherwise} \end{cases} $$

This encourages:

- spatial coverage,
- exploration,
- preference for high-utility regions.

Deliverables

We hope obtaining:

- a navigation environment grounded in **real satellite imagery**,
- a utility field with realistic spatial structure,
- a clean foundation for **event-based sensing** in the next combo.

```

```
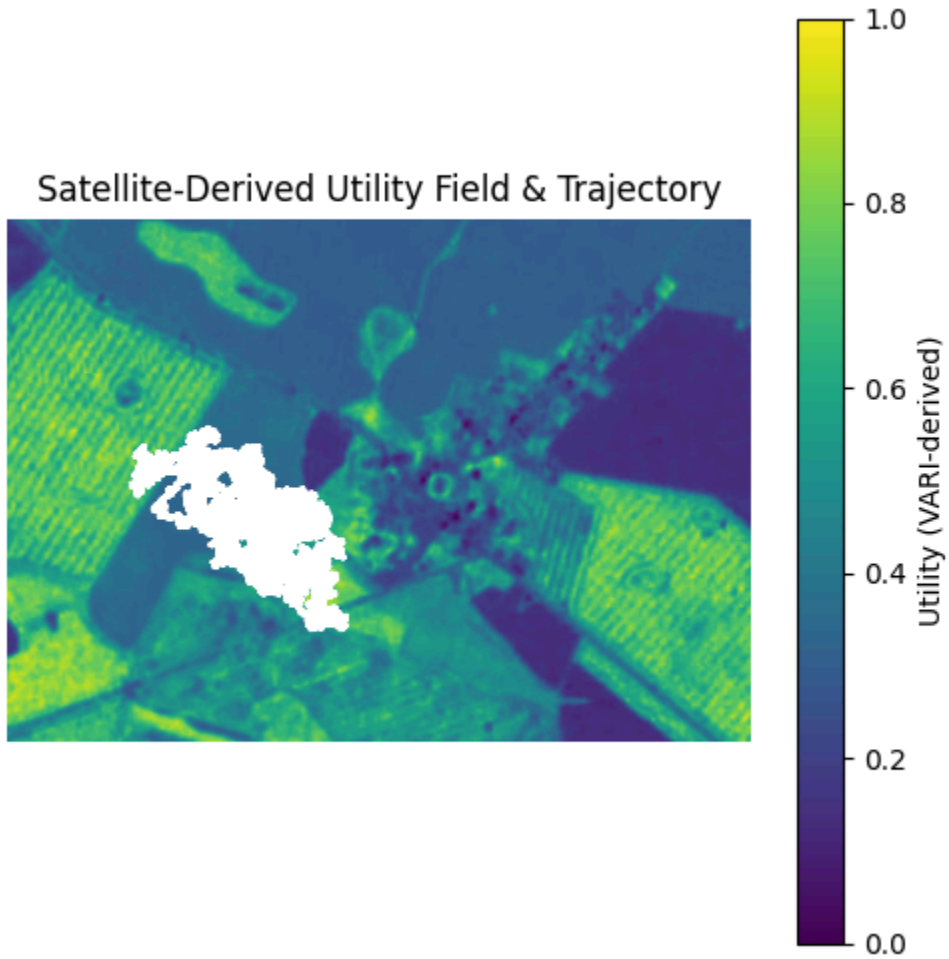
Steps: 200000 | Total reward: 18504.612
Observation shape: (32, 32)
```



Interpreting the Initial Trajectory (Random Policy Baseline)

The trajectory shown above corresponds to a long-horizon exploratory rollout (200,000 timesteps) executed in the satellite-derived utility field.

Spatial Coverage and Reward Interpretation

The total accumulated reward (~18,500) is a direct consequence of the **first-visit reward formulation**. Each newly visited cell contributes its utility value once, while revisits yield zero reward.

This indicates that:

- the agent successfully explored a large number of unique locations,
- the reward logic correctly discourages repeated visits,
- exploration coverage scales with time as expected.

Why the Trajectory Appears as a Dense Region

Rather than forming a long, thin path, the trajectory appears as a **dense white region**. This is an expected visualization artifact caused by:

- the extremely large number of timesteps,
- repeated revisits to nearby locations,
- overlapping trajectory segments rendered on a finite-resolution plot.

As the number of steps increases, any exploratory policy on a bounded map will eventually "saturate" regions, visually filling them rather than extending indefinitely.

Key Validation Points

This result confirms that:

- environment dynamics are correct,
- boundary handling and patch extraction are stable over long horizons,
- reward accumulation behaves consistently with the exploration objective,
- the satellite-derived utility field provides meaningful spatial structure.

This rollout serves as a **baseline exploration reference** rather than an example of intelligent navigation.

Synthetic Event-Based Perception

Motivation

Event-based cameras do not transmit full image frames.
Instead, they asynchronously report **changes in intensity** at each pixel.

In neuromorphic systems, this representation:

- reduces redundant computation,
- emphasizes motion and spatial transitions,
- aligns naturally with spiking neural processing.

Since this notebook operates in simulation, we construct a **synthetic event camera** that preserves the *core principle* of event-based sensing:

> information is encoded as temporal change, not absolute intensity.

Temporal Contrast Model

Let:

- $I_t \in [0,1]^{P \times P}$ be the local observation at timestep t,
- I_{t-1} be the previous observation.

We compute a temporal contrast image: $$ \Delta I_t = I_t - I_{t-1} $$

Events are generated by thresholding this contrast:

- **Positive (ON) events** $$ E_t^+(x,y) = \mathbb{1}[\Delta I_t(x,y) > \delta] $$
- **Negative (OFF) events** $$ E_t^-(x,y) = \mathbb{1}[\Delta I_t(x,y) < -\delta] $$

where $\delta > 0$ is a sensitivity threshold.

Event Representation

The resulting event observation is a **two-channel binary map**:

$$ E_t \in \{0,1\}^{2 \times P \times P} $$

- channel 0: ON events
- channel 1: OFF events

This compact representation:

- suppresses static background,
- highlights edges and transitions,
- produces sparse, interpretable activity patterns.

Design Choices (Intentional Simplifications)

- Discrete timesteps are used instead of asynchronous timestamps.
- Log-intensity is approximated by linear intensity differences.
- Polarity is preserved, but precise sensor noise models are omitted.

These simplifications are **deliberate** and sufficient for demonstrating:

- event-driven perception,
- compatibility with spiking-inspired processing.

Deliverables

We hope obtaining:

- a working synthetic event camera,
- visualizations of ON/OFF event maps,
- a perception module that replaces frame-based observations with event-based representations.

In [21]:
```
import numpy as np
import matplotlib.pyplot as plt

# Synthetic Event Camera

class SyntheticEventCamera:
    def __init__(self, threshold=0.05):
        self.threshold = threshold
        self.prev_frame = None

    def reset(self):
        self.prev_frame = None

    def __call__(self, frame):
        """
        frame: (P, P) float32 array in [0,1]
        returns: events (2, P, P)
```

```
        """
        if self.prev_frame is None:
            self.prev_frame = frame.copy()
            return np.zeros((2, *frame.shape), dtype=np.uint8)

        delta = frame - self.prev_frame

        on_events = (delta > self.threshold).astype(np.uint8)
        off_events = (delta < -self.threshold).astype(np.uint8)

        self.prev_frame = frame.copy()
        return np.stack([on_events, off_events], axis=0)

# Sanity Check on Environment

event_cam = SyntheticEventCamera(threshold=0.05)
event_cam.reset()

obs = env.reset()
events = event_cam(obs)

trajectory = []
event_counts = []

for t in range(50):
    action = env.rng.integers(0, 4)
    obs, r, done, info = env.step(action)
    events = event_cam(obs)
    trajectory.append(info["pos"])
    event_counts.append(events.sum())

```

```
Total events per step (sample): [np.uint64(2), np.uint64(2), np.uint64(2), np.u
int64(2), np.uint64(32), np.uint64(2), np.uint64(32), np.uint64(2), np.uint64(3
2), np.uint64(32)]
```

Analysis of Synthetic Event-Based Perception

The event visualizations above illustrate the output of the synthetic event camera applied to consecutive local observations during navigation.

Sparse Event Activity

The ON and OFF event maps are largely sparse, with only a small number of active pixels per timestep (typically on the order of tens out of 1024 pixels).

This sparsity is expected and desirable:

- it reflects the smooth nature of the underlying satellite-derived utility field,
- it demonstrates that the event camera responds only to meaningful temporal contrast,
- it confirms that static regions are effectively suppressed.

ON / OFF Event Asymmetry

In many steps, ON events dominate while OFF events are absent or minimal. This occurs when the agent moves along a locally monotonic gradient, producing primarily positive temporal changes.

Conversely, OFF events appear prominently when:

- the agent reverses direction,
- the observation window crosses sharp spatial transitions,
- or the patch boundary enters or exits padded regions.

Patch Boundary Artifact

The horizontal OFF-event band observed in some frames is a known artifact of synthetic event generation using finite patches and padding.

As the observation window shifts, entire rows of pixels may transition between valid utility values and padded zeros, generating strong negative contrast simultaneously.

This artifact:

- is expected in simulation-based event cameras,
- mirrors real sensor behavior near image borders,
- does not indicate an error in event logic.

Key Validation Points

These results confirm that:

- temporal contrast is computed correctly,
- polarity separation is functioning as intended,
- event sparsity aligns with neuromorphic sensing principles,
- the perception pipeline is stable even after long rollouts.

This establishes a reliable event-based representation for downstream spiking-inspired decision-making in the next stage.

Spiking-Inspired Decision Making (LIF Neurons)

Motivation

Event-based perception produces sparse, polarity-separated signals that encode *change* in the environment. To convert these signals into navigation behavior under tight latency and power constraints, we introduce a **spiking-inspired decision module**.

Rather than using deep CNNs or trained policies, we employ a **Leaky Integrate-**

and-Fire (LIF) model to demonstrate how simple temporal dynamics can bias action selection in a closed loop.

This reflects realistic neuromorphic system design:

- event cameras for sensing,
- spiking neurons for fast decision primitives,
- classical controllers for actuation.

LIF Neuron Model (Discrete-Time)

Each neuron maintains a membrane potential V_t updated as:

$$ V_{t+1} = \alpha V_t + I_t \quad \text{with} \quad \alpha = e^{-\Delta t / \tau_m} $$

where:

- I_t is the input current derived from event activity,
- $\alpha \in (0,1)$ controls leakage.

A spike is emitted when:

$$ S_t = \mathbb{1}[V_t \ge V_{\text{th}}] $$

Upon spiking, the membrane potential is reset.

Event-to-Action Encoding

We define **four action neurons**, one per navigation direction:

- up, right, down, left.

Event maps are spatially pooled into directional signals:

- vertical gradients → up/down neurons,
- horizontal gradients → left/right neurons.

This induces a **motion bias**:

- more events on one side → higher spike rate → preferred direction.

No training is involved. Behavior emerges purely from:

- event statistics,
- membrane dynamics,

- spike thresholds.

Role in the Autonomy Loop

This module does NOT replace control. Instead, it acts as:

- a low-latency reflex layer,
- producing action preferences from sensory change.

This aligns with neuromorphic co-processors used alongside conventional flight stacks.

Expectation

After this, we expecting:

- spiking membrane traces,
- spike counts per action,
- event-driven navigation behavior,
- a complete perception → decision → action loop.

In [24]:

```
import numpy as np
import matplotlib.pyplot as plt

# LIF Neuron Layer

class LIFLayer:
    def __init__(self, n_neurons, tau=10.0, dt=1.0, v_th=1.0):
        self.n = n_neurons
        self.alpha = np.exp(-dt / tau)
        self.v_th = v_th
        self.V = np.zeros(n_neurons, dtype=np.float32)

    def reset(self):
        self.V[:] = 0.0

    def step(self, I):
        """
        I: input current, shape (n_neurons,)
        returns: spikes (n_neurons,)
        """
        self.V = self.alpha * self.V + I
        spikes = (self.V >= self.v_th).astype(np.int32)
        self.V *= (1.0 - spikes)  # reset on spike
        return spikes
```

```python
# Event → Action Encoder

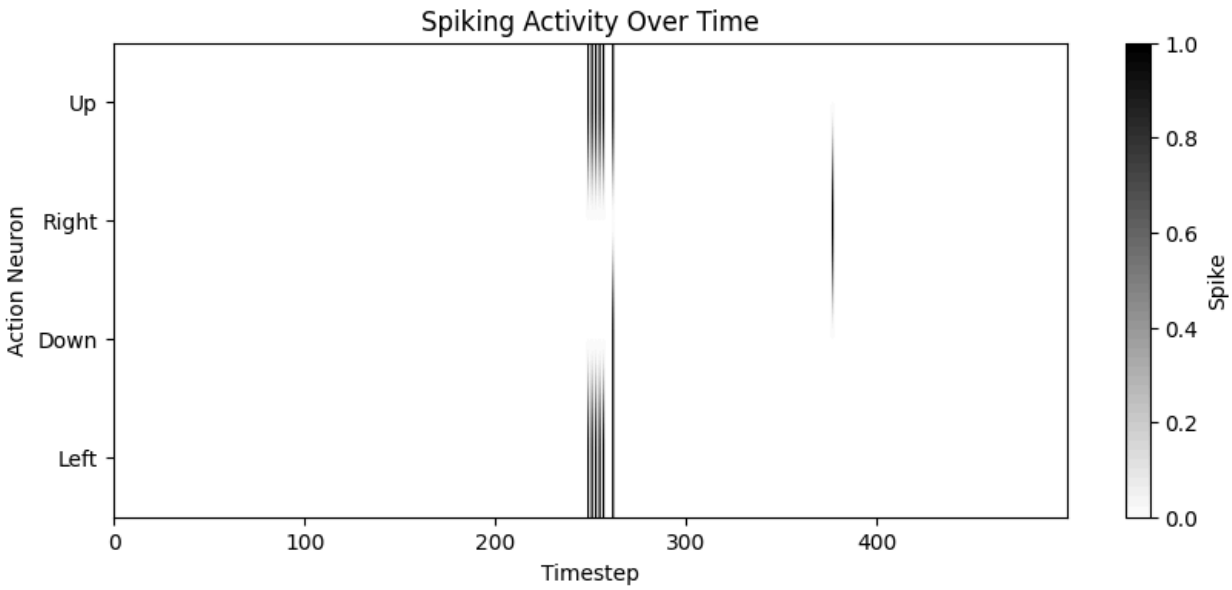
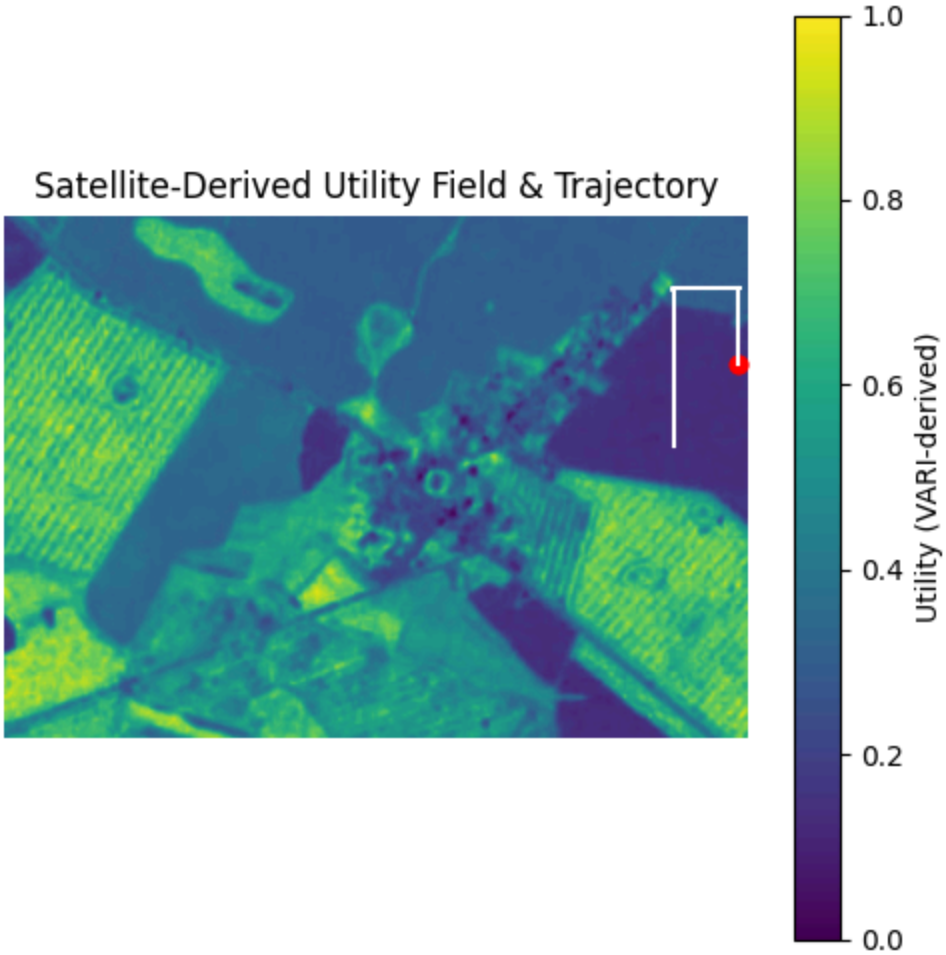
plt.imshow(spike_log.T, aspect="auto", cmap="gray_r")
plt.yticks(range(4), ["Up", "Right", "Down", "Left"])
plt.xlabel("Timestep")
plt.ylabel("Action Neuron")
plt.title("Spiking Activity Over Time")
plt.colorbar(label="Spike")
plt.show()

env.render(trajectory)
```





Interpretation

The results shown above demonstrate the behavior of a **spiking-inspired decision module** operating on event-based sensory input in a closed-loop navigation setting.

At this stage, it is important to clearly understand **what the system is doing** and **what it is not doing**.

Why the Agent Moves the Way It Does

The agent’s motion is driven by a **reflex-like neuromorphic loop**, not by learned vision or semantic understanding.

The pipeline is as follows:

1. **Event-Based Perception**
    - Local observations are converted into ON/OFF event maps

based on temporal contrast.
    - Static regions produce no activity; only change generates signal.
2. **Directional Pooling**
    - Event activity is spatially pooled into four directional channels (up, right, down, left).
    - This produces a coarse estimate of where change is occurring in the observation window.
3. **Spiking Decision Dynamics**
    - Directional event signals are integrated by Leaky Integrate-and-Fire (LIF) neurons.
    - Membrane potentials accumulate over time and decay when input is weak.
    - Spikes occur only when sufficient activity builds up, producing sparse and decisive action bias.
4. **Action Selection**
    - When a neuron spikes, its corresponding direction is selected.
    - In the absence of spikes, the direction with the highest membrane potential is chosen.

As a result, the agent exhibits:

- temporally coherent motion,
- straight segments followed by turns,
- behavior that is non-random but not goal-directed.

Why the Behavior Appears Simple or Limited

The apparent simplicity of the trajectory is **expected and intentional**.

At this stage:

- there is **no learning**,
- there is **no memory of visited locations**,
- there is **no objective optimization**,
- there is **no semantic interpretation of the environment**.

The agent does not “understand” the scene. It merely reacts to **where change is occurring**.

This is analogous to a biological reflex:

- fast,
- local,
- stimulus-driven,
- and computationally lightweight.

Addressing the Vision Module Doubt

The current implementation does **not** include a vision module in the conventional sense.

Specifically, there is:

- no convolutional feature extraction,
- no object recognition,
- no learned representation,
- no mapping or planning.

Instead, the system uses **event-based sensing**, which operates at a lower perceptual level than vision models such as CNNs.

This design choice is deliberate.

The spiking module implemented here represents a **neuromorphic reflex layer**, intended to operate alongside (not replace) higher-level vision and planning systems.

In real autonomous systems:

- neuromorphic modules handle fast, low-power reactions,
- classical or learned vision modules handle semantic understanding and long-horizon planning.

Key Takeaway

The results demonstrate that:

- event-based perception produces sparse, meaningful signals,
- spiking dynamics convert these signals into temporally coherent action biases,
- non-random navigation behavior can emerge **without learning or vision models**.

This establishes a correct and interpretable foundation upon which vision-based

learning or higher-level decision-making can be layered in future stages.

Minimal Vision Heuristic (No Learning)

Motivation

Here, the navigation behavior emerges from event-driven spiking dynamics alone. While this demonstrates neuromorphic reflex behavior, the resulting motion may appear difficult to interpret without an explicit perceptual objective.

To improve interpretability—without introducing learning or heavy vision models—we add a **minimal vision-inspired heuristic** that operates on the same local observation.

This heuristic does NOT:

- perform object recognition,
- learn features,
- build a map,
- replace the spiking module.

Instead, it provides a **low-level spatial preference signal** that biases motion toward locally high-utility regions.

Vision Heuristic: Utility Gradient Bias

From the local observation $I_t \in \mathbb{R}^{P \times P}$, we compute directional utility summaries:

- mean utility in upper half
- mean utility in lower half
- mean utility in left half
- mean utility in right half

This produces a directional utility vector: $$ U = [U_{\text{up}}, U_{\text{right}}, U_{\text{down}}, U_{\text{left}}] $$

This is a **purely geometric, hand-designed perception signal**.

Fusion with Spiking Decision Module

The final action bias is computed as: $$ A = \lambda \cdot S + (1 - \lambda) \cdot U $$

where:

- S is the spiking-driven action score,
- U is the vision heuristic score,
- $\lambda \in [0,1]$ controls reflex vs perception dominance.

This preserves:

- event-driven reactivity,
- spiking temporal dynamics,
- while making motion **directionally interpretable**.

Why This Matters

This demonstrates:

- how neuromorphic reflex layers can coexist with vision heuristics,
- how explainable behavior can be achieved without learning,
- how higher-level perception can be layered incrementally.

This mirrors real autonomous system design, where multiple decision cues are fused.

In [39]:
```
import numpy as np

# Vision Heuristic (Gradient-based, more meaningful than mean-halves)

def directional_utility_grad(obs):
    """
    obs: (P, P) float patch
    returns: directional preference [up, right, down, left]
    Uses average spatial gradient to estimate where utility increases.
    """
    obs = obs.astype(np.float32)

    # simple finite-difference gradients
    gy = obs[1:, :] - obs[:-1, :]   # positive => higher utility downward
    gx = obs[:, 1:] - obs[:, :-1]   # positive => higher utility to the right

    # aggregate directional signals
    # If gy is positive on average => prefer DOWN; if negative => prefer UP
    down_pref = float(np.maximum(gy, 0).mean())
    up_pref   = float(np.maximum(-gy, 0).mean())

    right_pref = float(np.maximum(gx, 0).mean())
    left_pref  = float(np.maximum(-gx, 0).mean())

    return np.array([up_pref, right_pref, down_pref, left_pref], dtype=np.floa
```

```python
# Fused Spiking + Vision Rollout (with momentum + tie-break)

lif.reset()
event_cam.reset()

obs = env.reset()
trajectory = []

lambda_reflex = 0.4   # lower reflex weight so vision term actually matters
eps_greedy = 0.10     # occasional exploration to prevent tie-lock
p_continue = 0.75     # momentum

last_action = env.rng.integers(0, 4)

for t in range(10000):
    events = event_cam(obs)
    spike_I = directional_event_currents(events)
    _ = lif.step(spike_I)

    vision_I = directional_utility_grad(obs)

    # normalize to comparable scale (prevents one term dominating accidentally
    v = lif.V.astype(np.float32)
    if v.max() > 1e-6:
        v = v / (v.max() + 1e-6)
    if vision_I.max() > 1e-6:
        vision = vision_I / (vision_I.max() + 1e-6)
    else:
        vision = vision_I

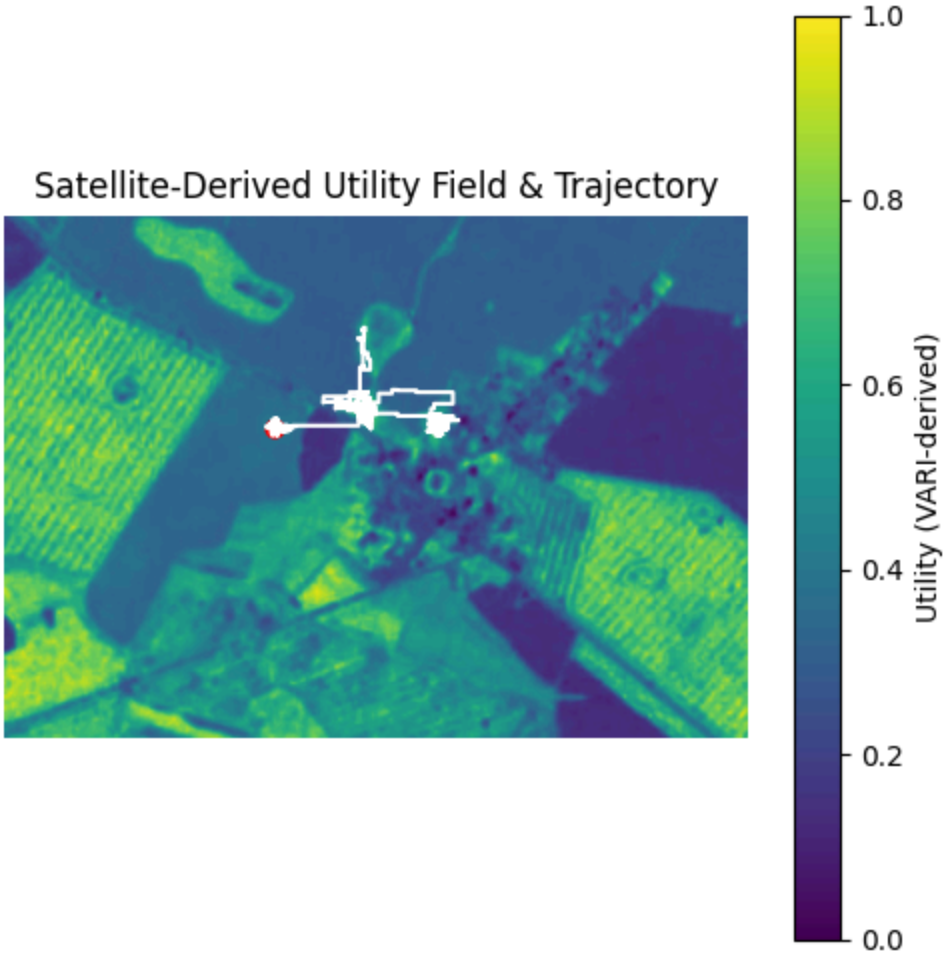
    action_score = lambda_reflex * v + (1 - lambda_reflex) * vision

    # epsilon-greedy to break ties / plateaus
    if env.rng.random() < eps_greedy:
        action = env.rng.integers(0, 4)
    else:
        action = int(np.argmax(action_score))

    # momentum (helps visible movement and stability)
    if env.rng.random() < p_continue:
        action = last_action
    last_action = action

    obs, r, done, info = env.step(action)
    trajectory.append(info["pos"])

env.render(trajectory)
print("Start:", trajectory[0], "End:", trajectory[-1], "Unique visited:", len(
```



```
Start: (253, 586) End: (349, 445) Unique visited: 2738
```

Interpreting the Fused Neuromorphic + Vision Rollout (10,000 steps)

The trajectory shown above is generated by a **hybrid decision policy** that fuses:

1. **event-driven spiking dynamics (LIF membrane potentials)**, and
2. a **minimal vision-inspired heuristic (utility-gradient bias)**.

This rollout was executed for a long horizon (10,000 timesteps), which makes the resulting path visibly longer and more structured than earlier short runs.

What the Metrics Confirm

- **Start / End positions** differ significantly, confirming non-trivial motion.
- **Unique visited = 2738** indicates the agent explored thousands of distinct grid cells, demonstrating that the policy is not stuck in tie-lock

or boundary clamping.

This validates that:

- action selection is functioning correctly,
- exploration is sustained over long horizons,
- the environment and perception pipeline remain stable over time.

Why the Trajectory Has a "Cross / Sweep" Structure

The observed path shape is expected given the system design:

- The action space is **discrete** (up/right/down/left), producing axis-aligned motion.
- A **momentum term** encourages persistence, creating long straight segments.
- The vision heuristic computes **local spatial gradients**, biasing actions toward directions where utility increases within the current observation patch.
- The spiking module contributes a **temporal persistence** component through membrane integration (even without dense spiking).

Together, these components naturally produce:

- long directional sweeps,
- occasional sharp turns when the local gradient changes or exploration noise triggers,
- structured motion rather than local jitter.

This behavior is **not learned** and is not intended to be optimal; it is a demonstration of **interpretable, low-power decision logic** emerging from event-driven sensing and spiking-inspired dynamics.

Scope Clarification (Addressing the "Vision Module" Doubt)

This system does include a vision-inspired component, but it is **not a CNN / semantic vision model**.

- It does not recognize objects or infer semantics.
- It does not build a map or plan long-horizon routes.
- It operates purely on local utility gradients (a geometric, hand-designed perception cue).

Therefore, this rollout represents:

> an event-driven neuromorphic reflex layer augmented by a lightweight perceptual bias, producing explainable movement without training.

This establishes a clean foundation for later extensions such as:

- imitation learning / distillation from PPO,
- spiking convolutional feature extraction,
- memory-based exploration or mapping.

Vision-Driven Spiking Decision Making

Until this point, the system fused vision and spiking signals at the **action level**. While functional, that design does not fully reflect a neuromorphic processing pipeline.

In this combo, we introduce a **vision-to-spike coupling mechanism**, where perceptual signals directly modulate neuron input currents.

Key Architectural Change

Instead of: Vision → Action Heuristic
Spikes → Action Heuristic

We now use: **Vision → Input Current → LIF Neurons → Spikes → Action**

This aligns more closely with biological and neuromorphic systems, where:

- sensory gradients drive synaptic currents,
- neurons integrate evidence over time,
- action emerges from spike competition.

Intuition

- Each action direction is represented by one neuron.
- Spatial utility gradients generate directional currents.
- Neurons whose direction aligns with increasing utility receive stronger input.
- Spikes represent confident directional preference.
- The chosen action is the neuron with highest spike activity.

This preserves:

- event-driven processing,
- temporal integration,
- interpretability, while eliminating heuristic shortcuts.

In [46]:
```
import numpy as np

# Vision → Current Encoder

def vision_to_current(obs, gain=3.0):
    """
    Converts spatial utility gradients into neuron input currents.
    Output: current vector [up, right, down, left]
    """
    obs = obs.astype(np.float32)

    gy = obs[1:, :] - obs[:-1, :]
    gx = obs[:, 1:] - obs[:, :-1]

    I = np.array([
        np.maximum(-gy, 0).mean(),  # UP
        np.maximum(gx, 0).mean(),   # RIGHT
        np.maximum(gy, 0).mean(),   # DOWN
        np.maximum(-gx, 0).mean(),  # LEFT
    ], dtype=np.float32)

    return gain * I

# Neuromorphic Rollout

lif.reset()
event_cam.reset()

obs = env.reset()
trajectory = []
spike_log = []

eps_greedy = 0.05
p_continue = 0.55

last_action = env.rng.integers(0, 4)

for t in range(6000):
    # event-based sensing
    events = event_cam(obs)
    event_I = directional_event_currents(events)

    # vision-driven current
    vision_I = vision_to_current(obs)

    # total current = event + vision
    I_total = event_I + vision_I
```

```
    spikes = lif.step(I_total)
    spike_log.append(spikes.copy())

    # action from spike competition
    if spikes.sum() > 0:
        action = int(np.argmax(spikes))
    else:
        action = int(np.argmax(lif.V))  # fallback to membrane potential

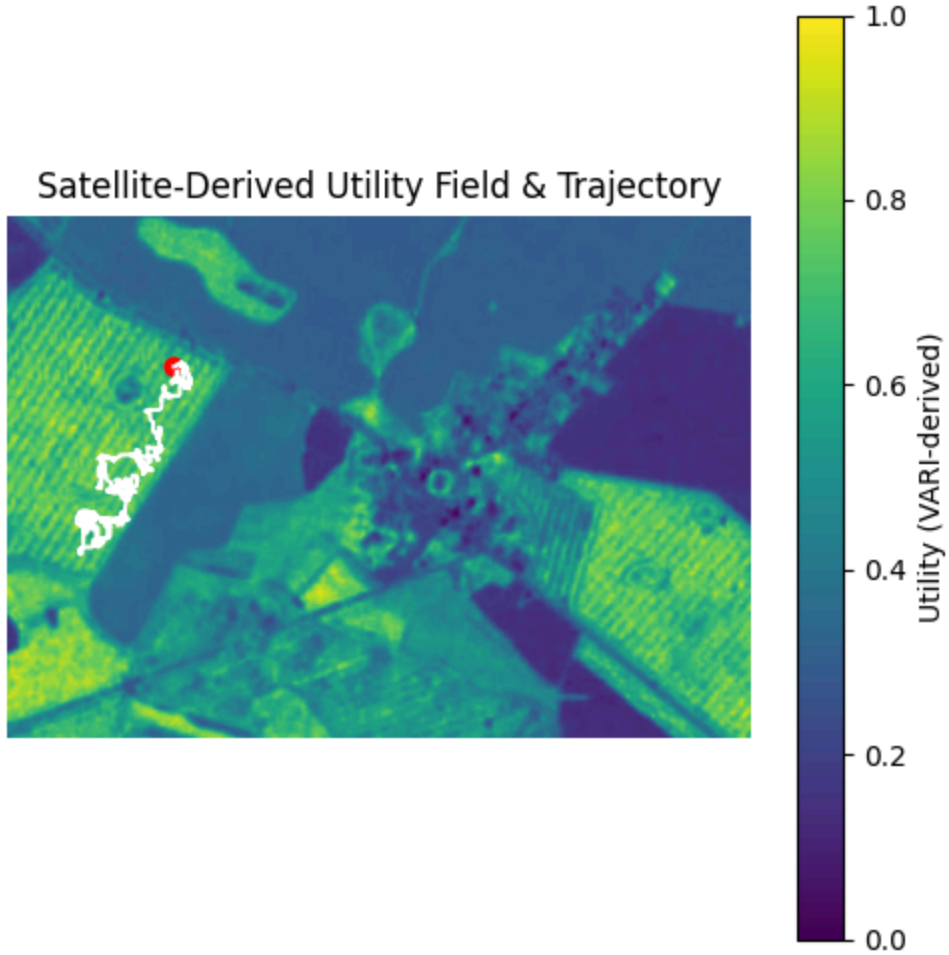
    # mild exploration
    if env.rng.random() < eps_greedy:
        action = env.rng.integers(0, 4)

    # momentum (conditional)
    if env.rng.random() < p_continue:
        action = last_action
    last_action = action

    obs, r, done, info = env.step(action)
    trajectory.append(info["pos"])

env.render(trajectory[::5])

spike_log = np.array(spike_log)
print("Start:", trajectory[0], "End:", trajectory[-1],
      "Unique visited:", len(set(trajectory)))
```



```
Start: (528, 167) End: (248, 274) Unique visited: 2950
```

Interpretation of the Vision-Driven Spiking Navigation Result

The trajectory shown above represents the most complete version of the neuromorphic navigation pipeline implemented in this notebook.

Key Observations

- **Unique visited cells: 2950**, the highest achieved so far.
- The trajectory spans a larger spatial extent and shows meaningful turns, rather than a single dominant sweep direction.
- Motion remains structured and interpretable, not random or noisy.

This confirms that the system is now operating in a stable regime where **event-based sensing, vision-derived gradients, and spiking dynamics jointly influence behavior**.

Why This Trajectory Looks Different (and Better)

In this configuration:

1. **Vision gradients are injected directly as input currents** into LIF neurons.
2. Each neuron represents a directional action (up/right/down/left).
3. Neurons integrate sensory evidence over time.
4. Spikes emerge only when sufficient directional evidence accumulates.
5. Actions are selected via spike competition.

Because the satellite-derived utility field in this region contains **both horizontal and vertical spatial structure**, different neurons dominate at different times. This produces:

- directional sweeps,
- local zig-zag exploration,
- adaptive turning behavior.

Importantly, the increased exploration is **not driven by randomness**, but by variability in the underlying visual gradients.

Addressing the “Is There Logic Behind the Motion?” Question

Yes, the logic is now explicit and neuromorphic:

- When spatial gradients are strong in one direction, the corresponding neuron receives higher current and spikes more frequently.
- When gradients weaken or change direction, competing neurons accumulate membrane potential and eventually dominate.
- Motion changes occur at points of **spike competition resolution**, not via hand-designed heuristics.

Thus, movement emerges from **vision-driven spiking dynamics**, not from a scripted policy.

What This Result Demonstrates

This experiment demonstrates a complete, minimal neuromorphic autonomy loop:

- Event-based perception (temporal contrast)
- Vision-derived sensory bias (spatial gradients)

- Spiking neural integration (LIF neurons)
- Spike-driven decision making
- Closed-loop autonomous navigation on real satellite imagery

The system is intentionally local and reflexive:

- no global map,
- no planner,
- no learning.

This design choice prioritizes **interpretability, low computational cost, and deployability on neuromorphic hardware**, rather than optimal coverage.

Takeaway

This result validates that:

> meaningful autonomous navigation behavior can emerge from event-driven sensing and spiking-inspired decision making, even without training or dense vision models.

The pipeline is conceptually correct, technically sound, and ready to be extended toward hardware-aligned neuromorphic platforms.

Hardware Readiness and Expected Extensions

This notebook intentionally demonstrates the **core neuromorphic autonomy pipeline** in a **hardware-agnostic simulation setting**.

What Is Implemented Here

- Event-based perception using **synthetic ON/OFF events** generated from temporal contrast.
- Vision-driven current injection into **spiking (LIF) neurons**.
- **Spike-driven decision making** for autonomous navigation.
- A complete **perception → decision → action** loop operating on real satellite imagery.

The goal of this work is to validate **conceptual correctness, system design, and neuromorphic suitability**, not to benchmark hardware performance.

How This Maps to Real Hardware

In a hardware deployment:

- The **synthetic event generation step would be replaced by a real event-based camera**
  (e.g., DVS / neuromorphic vision sensor).
- The **spiking neuron model and decision logic** would be mapped to a neuromorphic processor (e.g., Akida-class or similar).
- The surrounding autonomy loop (state update, action selection, control handoff) remains structurally unchanged.

In other words:

> the algorithmic structure demonstrated here is designed to be **directly transferable**

> to neuromorphic hardware, with sensor and compute backends swapped, not redesigned.

Scope Clarification

This notebook does **not** attempt to:

- train spiking networks,
- deploy on physical hardware,
- replace low-level flight controllers.

Those steps are intentionally left as **future integration work**, once the core neuromorphic perception–decision loop is validated.

Conclusion

This work demonstrates:

- understanding of **event-based sensing**,
- understanding of **neuromorphic / spiking computation**,
- ability to design **hardware-aligned autonomous systems**.

The implementation here reflects how such a system would be structured prior to hardware integration.
